Lecture 11b: Mixed models for discrete data (VER Ch. 22)

Index Page

- assignment study quality **due Friday March 21st at 5pm**
- presentation and discussion Tuesday March 25th
- NO CLASS FRIDAY MARCH 28th
- quiz clustered data?

Random effects logistic regression

- animal diseases observed in several herds, then the probability "p_i" of the i^{th} animal being diseased is
  - $\text{logit}(p_i) = \beta_0 + \beta_1 * X_{1i} + ... + \beta_k * X_{ki} + u_{\text{herd(i)}}$
    - $u_{\text{herd(i)}} \sim Normal(0, \sigma^2_{herd})$
    - σ^2_{herd} = variability among herds (on the logit scale)
    - only difference from ordinary logistic regression is the herd random-effects term
  - Note: probability of the predicted outcome (p_{ij}) is conditional on the random effect (u_j)
    - predicted value for any individual is the predicted value given that it is in herd "j"

Example – pig pneumonia data - pig_adg.dta

- outcome = pn, predictor = ar_g1 (ar>1)

  Farm (15) (range: 14-28)

  - Y_{ij} = pn status (0/1) of pig "i" in herd "j"

Simple analysis

- 2 x 2 analysis

```
. cc pn ar_g1
                                                        Proportion
                 |   Exposed   Unexposed  |      Total     Exposed
-----------------+------------------------+------------------------
           Cases |       109          77  |        186      0.5860
        Controls |        66          89  |        155      0.4258
-----------------+------------------------+------------------------
           Total |       175         166  |        341      0.5132
                 |                        |
                 |      Point estimate    |    [95% Conf. Interval]
                 |------------------------+------------------------
      Odds ratio |         1.908894       |     1.21155    3.009556 (exact)
 Attr. frac. ex. |         .4761365       |     .1746111    .6677251 (exact)
 Attr. frac. pop |         .2790262       |
                 +-----------------------------------------------
                               chi2(1) =     8.69  Pr>chi2 = 0.0032
```

  - unconditional OR is 1.91 ($\beta = 0.647$)

- ordinary logistic regression

```
. logit pn ar_g1

Logistic regression                               Number of obs   =        341

```

Interpretation of parameters

Cluster-specific vs population-averaged interpretation

Example – Use of cistern and household water tx on presence of GI symptoms in the family

- Water Tx= water chlorination
  - cluster-specific
    - effect of water tx to a family in a specific community
  - population-averaged
    - effect of water tx across all community
    - difference in risk of GI across all communtities between tx and non-tx groups (households)
- Cistern
  - cluster specific
    - communities with and without cisterns
      - difference in risk of GI between presence or not of cistern in that municipality
    - communities without cisterns
      - no meaningful interpretation
  - population-averaged
    - difference in risk of GI between presence or not of cisterns across all communities

Pig dataset

- coefficient parameters
  - cluster-specific
    - β = effect in a individual if changed value of X
      - within a cluster
    - mixed (random-effects) models
      - β_1 = 0.437 (SE=0.258, P=0.091)
        - reduced effect, borderline significant
      - effect of ar_g1 when comparing two pigs in the same farm
  - population-averaged
    - β = average effect of X in population
    - estimates closer to null
    - overall comparison of pigs with and without ar_g1 from any herd

$$\beta_{PA} \approx \frac{\beta_{SS}}{\sqrt{(1+0.346*\sigma^2_{herd})}} = \frac{0.437}{\sqrt{(1+0.346*0.877)}} = 0.383$$

- variance parameter
  - σ_h^2 = 0.877 (SE = 0.432)
    - substantial variation between farms in logit of pn
    - level of logit(pn) in pigs with ar_g1=0
      - most farms between 0.02 +/- 1.96*.94 = -1.82 to 1.86
      - prev. between 14% and 87%
  - also can be interpreted as cluster median Odds Ratio
    - more details in text

Random effects Poisson regression

- overdispersion in count data is common
  - options
    - add overdispersion parameter to the model
    - negative binomial model
      - appropriate if overdispersion not due to clustering
    - Poisson models with random effects
    - negative binomial model with random effects
- Poisson model with random effects
  - $\log(\lambda_i) = \beta_0 + \beta_1 * X_{1i} + ... + \beta_k * X_{ki} + u_{\text{herd(i)}}$
    - $Y_i \sim Poisson(\lambda_i * par_i)$
    - $u_{\text{herd(i)}} \sim \text{Normal}(0, \sigma^2_{herd})$

Example: tuberculosis data - tb_real.dta

- 30 herds
- 134 groups of animals defined by:
  - type: dairy (15); beef (58); cervid (52); other (9)
  - age: 0-12 mo (37); 12-24 mo (38), > 24 mo (59)
  - sex: female (74), male (60)
  - outcome: # TB reactors
  - exposure: # animal-days at risk

Fixed effects and random effects models

Variable	*Poisson*		*Negative Binomial*		*Poisson rand. (Normal)*	
	β	SE	β	SE	β	SE
Type						
beef	0.442	(0.236)	0.605	(0.675)	-0.394	(0.333)
cervid	1.066	(0.233)	0.666	(0.684)	-0.238	(0.487)
other	0.438	(0.615)	0.800	(1.119)	-0.104	(0.800)
Gender						
male	-0.362	(0.195)	-0.057	(0.405)	-0.339	(0.208)
Age						
12-24	2.673	(0.722)	2.253	(0.903)	2.717	(0.747)
> 24	2.601	(0.714)	2.481	(0.882)	2.467	(0.726)
Constant	-11.690	(0.740)	-11.181	(1.061)	-11.055	(0.830)
α	-		1.740		-	
σ_{herd}	-		-		1.299	
LL	-238.7		-157.7		-143.7	
Dispersion	8.71		2.95			

- only age was stat. sig., estimates for age reasonably consistent
  - Poisson with random effects appears to fit better

- also Negative binomial models with random effects
  - see VER22.4.3

Interpretation of the parameters

- fixed effect coefficients
  - no distinction between population averaged and subject specific interpretation (except for constant – rarely of interest)
  - CS -> $IRR_{>24\ mo} = \exp(2.467) = 11.78$
    - effect when comparing two groups from the same herd
  - PA -> $IRR_{>24mo} = \exp(2.443) = 11.51$
    - effect when comparing two groups from any herd

- variance parameters ($\sigma_{herd} = 1.299$)
  - approximate range in estimate of incidence rate across herds (for baseline animal: dairy, female, 0-12 mo) was:
    - -11.055 +/- 1.96*1.299 = -13.601 to -8.509
    - 1.2 to 202 per 1,000,000 animal-days at risk

Estimation procedures

- not straightforward, various approaches
- ML estimation is becoming the "norm"
  - numerically difficult for large datasets
- quasi-likelihood
  - uses iterative weighted least squares
  - can get cluster-specific (PQL) or population-averaged estimates (MQL)
    - eg. MlwiN
  - some disadvantages
    - no likelihood based statistics
    - biases estimates (particularly of variance estimates - biased towards the null)

Approaches for clustered data

Method	Adjust β	Adjust SE	>1 level	ICC	Comments
Mixed models	Y	Y	Y	Y	
FE	Y	Y	N	N	no cluster-level predictors
Stratified	Y	Y	N	N	binary data
Dispersion	N	Y	N	N	no-within cluster predictors and not for continuous data
Robust SE	N	Y	N	N	adjust for other model violations (continuous data)
General Est. Eq	Y	Y	(N)	(Y)	population average parameters (discrete data)
